1 Behavioral Effects in Magnitude Estimation

Magnitude estimation is subject to noise that arises from external sources i.e. the statistics of the environment and internal sources i.e. neural representation of the input and the behavior. Across sensory modalities, characteristic behavioral effects are identified (Petzschner et al. 2015). The most prominent observation is a regression to the mean of the stimulus range, i.e. small stimuli are overestimated whereas large stimuli are underestimated (*regression effect*). This effect intensifies for ranges with larger stimuli (*range effect*). For larger stimuli the standard deviation of estimates increases monotonically (*scalar variability*). Finally, the recent history of stimuli presentations influences the current stimuli estimation (*sequential effect*). All effects mentioned above are displayed in Fig. 1.

Modality-independence of these effects suggests the existence of a common underlying principle or processing mechanisms, that would explain e.g. a optimal strategy for unreliable judgments due to noise (in stimuli and estimates).

Figure 1: **Behavioral Effects** *Regression effect*: in a range of stimuli large stimuli are underestimated, and small stimuli are overestimated which results in a regression to the mean of the range. *Range effect*: the regression to the mean gets more pronounced for ranges that comprise larger stimuli. *Scalar variability*: the standard deviation of the reproduced magnitude grows linearly with larger ranges. *Sequential effects*: the history presented stimuli (e.g. ascending or descending order) has an influence on the reproduced magnitude. Figure from Petzschner et al. 2015.

During time perception and time reproduction experiments, neural activity displays characteristic trajectories in a low-dimensional space (Meirhaeghe et al. 2021, Wang et al. 2018, Henke et al. 2021). The neural trajectories are consistently influenced by prior beliefs. Flexible motor timing can be achieved by controlling the speed of neural dynamics (Sohn et al. 2019, Wang et al. 2018). Further, it has been found that neural activity in anticipation of a delayed response reaches a fixed threshold with a rate inversely proportional to delay

period (Murakami et al. 2014, Mita et al. 2009). Wang et al. 2018 proposed a potential neural mechanism for speed control. Based on that mechanism Egger et al. 2020 developed an extended circuit model for sensorimotor timing.

2 Model Description

2.1 Basic Circuit

Flexible speed control can be achieved by a simple model consisting of three units, u, v, y that represent population activity. The dynamics of u, v , and y are defined as follows:

$$\begin{aligned}\tau \frac{du}{dt} &= -u + \theta(W_{uI}I - W_{uv}v + \eta_u) \\ \tau \frac{dv}{dt} &= -v + \theta(W_{vI}I - W_{vu}v + \eta_v) \\ \tau \frac{dy}{dt} &= -y + W_{yu}u - W_{yv}v + \eta_y\end{aligned}\tag{1}$$

Two units, u and v receive a tonic symmetric input I ($W_{uI} = W_{vI} = 6$) and are mutually inhibiting ($W_{uv} = W_{vu} = 6$). The inputs to u and v are governed by a sigmoidal activation function $\theta(x) = \frac{1}{1+\exp(-x)}$. y denoted the output unit, which receives excitatory input from u and inhibitory input from v ($W_{yu} = W_{yv} = 1$) resulting in a ramp-like activity of y . All three units have a time constant $\tau = 100ms$. Stochastic synaptic inputs are modeled as independent white noise η_u, η_v, η_y with standard deviation σ . Initial conditions of u, v and y have been optimized for in Egger et al. 2020 and are set to $u_0 = 0.7, v_0 = 0.2, y_0 = 0.5$.

Depending on the input I , the system shows different dynamics. For low levels of I ($0 < I < 0.5$) the system has three fixed points (two stable, one unstable at $u = v$) and y ramps up faster the higher input I . For intermediate values of I ($0.5 < I < 1$) the system still shows three fixed points of the same sort as in the low input regime but y ramps up with a slope that is inversely proportional to the input I (y ramps up slower the higher input I , see schematic in Fig. 2a, b). For high I ($1 < I$) the system has one stable fixed point (at $u = v$) and y ramps down faster for higher I . Thus, the speed at which the output y evolves can be controlled by the input I (Fig. 2b) and determines the time interval after which y reaches a fixed threshold y_0 . In interval reproduction experiments, reaching a threshold y_0 can be understood as movement initiation time which can be

controlled for by adjusting I . In this report, the intermediate input regime is explored: higher inputs results in a shallower slope of y , such that the threshold y_0 is reached after a longer time interval.

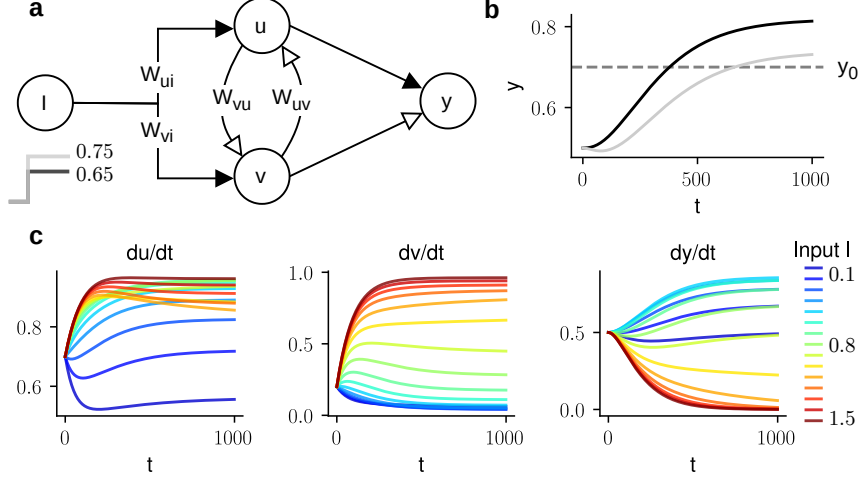

Figure 2: Basic Circuit and Input Regimes (a) u and v share a common input I . Dynamics for example input $I = 0.75$ in gray and $I = 0.65$ in black are plotted in (b). The input is governed by weights W_{uI} and W_{vI} . The two units have reciprocal inhibitory connections with weights W_{uv} and W_{vu} that determine the inhibitory strength. Both project to the output unit y with an excitatory connection from u and an inhibitory connection from v . Excitatory and inhibitory connections are shown by filled and open arrows, respectively. (b) Dynamics of y for intermediate regime with input $I = 0.75$ in gray and $I = 0.65$ black. There is an inverse relation of input strength and slope. With higher input, the threshold at 0.7 (dashed line) is reached after a longer time interval. (c) Dynamics of u, v, y for inputs from $0.1 \leq I \leq 1.5$ are shown. Initial conditions are set to $u_0 = 0.7, v_0 = 0.2, y_0 = 0.5$. With these initial conditions and values of $I \geq 0.5$, the relation of steady state activity of y (and slope to reach the steady state) is inverse to I (intermediate and high I regime). For values $I \leq 1$ the activity of y ramps down (yellow corresponds to $I = 1$). For $I < 0.5$ the steady state (slope) is smaller the smaller I (low I regime, dark blue).

2.2 Update Mechanism and Experiment Procedure

Basic interval reproduction experiments can be designed with only two epochs: a measurement epoch that has the duration of the stimulus interval and a reproduction epoch that starts immediately after the measurement epoch (Fig. 3b). The basic circuit described above is modified to perform interval reproduction (see Figure 3a for schematic of modified circuit). The relation of input I with

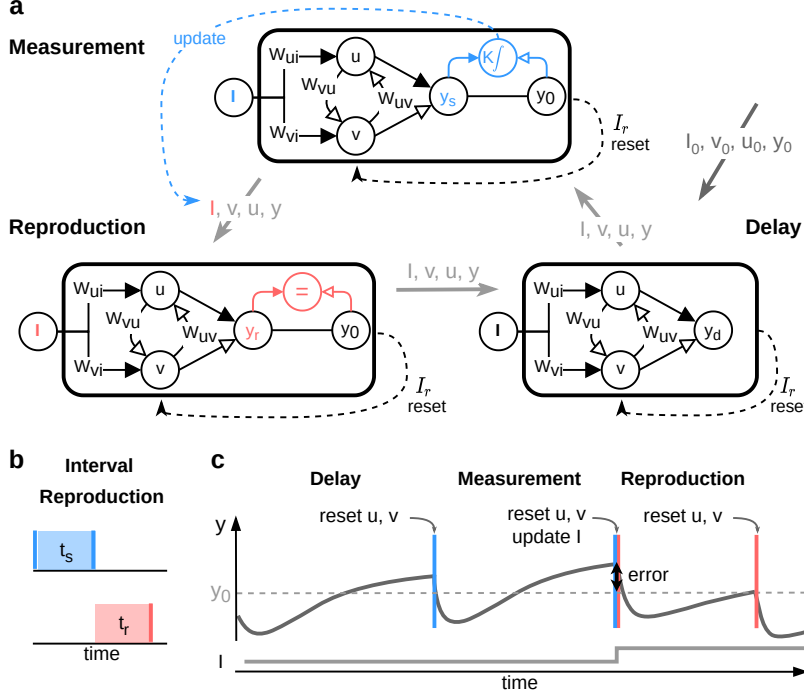

Figure 3: **Extended Circuit for Experiment Simulation** (a) The circuits for measurement, reproduction and delay epoch are displayed. All circuits comprise the same basic structure with different additional elements that are unique for the epoch. Initial values of u, v, y and I are fed into the delay circuit for the duration of the initial interval. u and v are reset with a transient input I_r before end values of u, v, y and I are transferred to the measurement circuit as new initial conditions. After the duration of the stimulus interval the difference between y and the threshold y_0 is used with the memory parameter K to update I together with another reset of u and v . The values are transferred with all other variables to the reproduction circuit. The reproduction epoch ends when y reaches the threshold y_0 from below. Before the presentation of another stimulus interval, there is again a delay period with no update of I . The reset mechanism enables the model to simulate an arbitrary number of stimulus intervals. Adapted from Petzschner et al. 2015. (b) Interval reproduction experiment with stimulus interval t_s (blue) and reproduction t_r (red). (c) Schematic of a trial with one stimulus interval. After a delay epoch u and v are reset. The measurement epoch lasts for the duration of the stimulus interval t_s . y should reach the threshold y_0 (dashed line) at exactly the time the stimulus interval ends. The threshold was crossed well before the end of the interval and at the end of the measurement epoch, the error in y_m to the threshold y_0 is used to update I . To reach the threshold at a later time, I is increased, which reduces the slope of y in the reproduction epoch. After the reset of u and y and the update of I the reproduction ends when y reaches the threshold. The time after the reset and update until the threshold crossing denotes the reproduced interval t_r .

the slope of the ramping activity of y is used in combination with a fixed threshold y_0 . By adding an update mechanism that flexible adjusts I , the threshold crossing of y can be delayed or moved to earlier times. This way, measuring and reproducing an interval is done predicatively, by adjusting the slope of the ramp such that the output reaches the threshold after the intended time. In the model the measurement epoch is fixed to the stimulus interval t_s , and the reproduction epoch ends, when y reaches the fixed threshold y_0 from below. The time from the end of the measurement epoch until the threshold-crossing of y yields the reproduced time interval t_r that is aimed to equal the stimulus interval t_s (Fig. 3c).

The following update mechanism of I is based on the intermediate input regime, that shows an inverse relation of I to the slope of y (Fig. 2b). The error signal is determined at the end of the measurement epoch and is composed of the difference of y to the threshold y_0 . If the threshold y_0 is not reached during the measurement epoch, the slope has to be adjusted, such that y ramps up faster to reach the threshold at exactly the time of the stimulus interval. For a steeper slope, I is reduced. If y crossed the threshold before the measurement epoch ends, so is above y_0 by the end of the stimulus interval, the slope needs to be reduced in order to reach the threshold at a later time in the reproduction. For a shallower slope, I is increased (Fig. 3c). I is adjusted according to the error $(y - y_0)$, weighted by a memory parameter K right at the end of the measurement epoch.

$$\tau \frac{dI}{dt} = sK(y - y_0) \quad (2)$$

The update of I is only active for a pulse between the measurement and reproduction epoch ($s = 1$) and inactive for all other times ($s = 0$). Further, u and v receive a transient input pulse I_r to reset the dynamics for the subsequent epoch (Fig. 3c).

$$\begin{aligned} \tau \frac{du}{dt} &= -u + \theta(W_{uI}I - W_{uv}v + \eta_u - I_r) \\ \tau \frac{dv}{dt} &= -v + \theta(W_{vI}I - W_{vu}u + \eta_v + I_r) \end{aligned} \quad (3)$$

Resetting the dynamics after the reproduction epoch enables the model to simulate an arbitrary number of stimulus intervals. Before a new stimulus presentation there is a delay period: In the beginning of an experiment trial with a

sequence of stimuli there is an initial interval with the initial values of u, v, y and an initial input I_0 (Fig. 3c). This additional interval in the beginning of the trial allows the model to get closer to steady-state before the stimulus presentation starts. Reproductions that do not reach the threshold in a certain time span (twice the stimulus interval) are classified as timeout trials. If the threshold is crossed particularly early, the trial is also classified as (early) timeout trial (crossing before 0.2 of stimulus interval).

To simulate variability in the reproductions as it is found in real data, noise is added to u, v and y in the implementation. In data an monotonic increase of the standard deviation of reproductions is found (*scalar variability*). If noise levels in the model are too high ($\sigma > 0.25 * I$) the standard deviation of reproductions is not growing monotonically with σ (Egger et al. 2020). For an example trial with a sequence of stimuli see Figure 4.

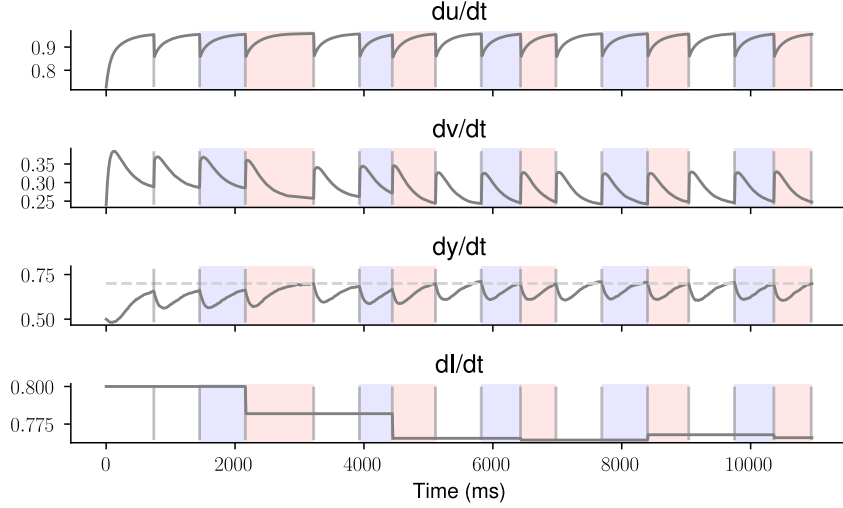

Figure 4: **Experiment Simulation** Example trial with a sequence of five stimulus intervals (700, 500, 600, 700, 600 ms). Initial values are set to $u_0 = 0.7, v_0 = 0.2, y_0 = 0.5, I_0 = 0.8$, other parameters are $\sigma = 0.01$, the initial duration of 750 ms and a 700 ms delay period before new stimuli. The dynamics of u, v, y and I are displayed over time. The threshold is set to $y_0 = 0.7$ (dashed line). The first stimulus interval is reproduced poorly as the system needs more trials to adapt the initial I_0 to a suitable range (reproduced times 1040, 650, 530, 620, 570 ms).

3 Implementation of the Model

All simulations and analysis were performed with Python 3.9.7. For simulating the dynamics of u, v, y and I Euler’s method was used with a step size Δt set to 10 ms. The reset mechanism of u and v is switched on for one time step after every epoch and the update mechanism of I is switched on for one time step after the measurement epoch only. Noise is independently sampled for every time step from a Gaussian distribution with standard deviation σ

4 Supplements

4.1 Code

The code consists of a Base Simulation with the Euler implementation for the dynamics of u, v, y and I . Time steps of each epoch (or one time step for update/reset pulse between epochs) is fed into the network in `BaseSimulation` and results are joint to the course of the trial in `trial_update`. Two kinds of experiments are implemented. An interval reproduction experiment, as described in this report is implements in `experiment_simulation`. Parallel simulations of one run (delay, measurement, reproduction epoch) is implemented in `parallel_simulation`. Both rely on `BaseSimulation` (for an overview of code structure see Figure 5)
